VelociWatch: Designing and Evaluating a Virtual Keyboard for the Input of Challenging Text

ABSTRACT

Virtual keyboard typing is typically aided by an auto-correct method that decodes a user's noisy taps into their intended text. This decoding process can reduce error rates and possibly increase entry rates by allowing users to type faster but less precisely. However, virtual keyboard decoders sometimes make mistakes that change a user's desired word into another. This is particularly problematic for challenging text such as proper names. We investigate whether users can guess words that are likely to cause auto-correct problems and whether users can adjust their behavior to assist the decoder. We conduct computational experiments to decide what predictions to offer in a virtual keyboard. We design a smartwatch keyboard named VelociWatch. Novice users were able to use the features of VelociWatch to enter challenging text at 17 words-per-minute with a corrected error rate of 3%. Interestingly, they wrote slightly faster and just as accurately on a simpler keyboard with limited correction options. Our finding suggest users may be able to type difficult words on a smartwatch simply by tapping precisely without the use of auto-correct.

INTRODUCTION

Text entry is a ubiquitous computing activity. As interaction moves from desktop computers to mobile phones, smartwatches, and optical see-through head-mounted displays, the need for fast and accurate text entry remains. A particular challenge is the inherently noisier input that a text entry system has to deal with as text entry methods move beyond physical full-sized keyboards. Such physical keyboards accommodate ten-finger typing and provide tactile feedback. When such keyboards are transplanted to small touchscreens, the lack of tactile sensation feedback and small form factor result in increased noise as users' input becomes less precise.

A popular solution is to use an auto-correct algorithm to rectify typing mistakes. The algorithm's job is to infer the most likely intended text from a user's noisy input. When this method
Figure 1. Entering text on the VelociWatch keyboard.

is probabilistic it is called a *decoder*. The decoder searches for the most probable text hypothesis given an uncertain and noisy *observation sequence*. This is possible because natural languages are highly redundant with most letter sequences being very improbable. Valid letter sequences can be captured by a statistical *language model*. The decoder's search for the most likely hypothesis is guided by this language model.

A well-designed decoder can help users reduce their error rate. This may also increase their entry rate by allowing faster and less precise typing. However, decoding can also result in unexpected results. When the decoder is carrying out its search, it is relying heavily on its language model. Thus if the user's intended text is similar to the text the language model has been trained on, the probability is high that the decoder will return the correct text. The flip-side is that if the user is writing text that is not well-represented in the language model, the decoder may return erroneous text. This results in the user being unexpectedly exposed to an incorrect word, which has to be manually corrected. This "auto-correct trap" [30] increases error rates, reduces entry rates, and increases user frustration.

To investigate how to help users avoid and correct recognition errors, we created VelociWatch (Figure 1). VelociWatch is a virtual keyboard optimized for the input of challenging text.

Challenging Text Input

We specifically want to study interface designs that help users avoid or fluidly correct auto-correction errors. However, most text entry evaluations have users copy easy to remember text such as the MacKenzie phrase set [20] or the Enron mobile data set [28]. As we will show, these phrase sets are quite predictable under a well-trained language model. Combining a good language model with a high-performance decoder results in user evaluations in which participants rarely face recognition errors. Thus we first design a new phrase set containing text that is harder for a decoder to infer, thus serving as a more challenging task for evaluating interfaces.

Aside from eliciting challenging text, we also wanted to collect data with substantial input noise. Thus we conducted our

investigation on a smartwatch. The small form factor makes precise typing difficult. Nevertheless, it is feasible to type on a full QWERTY virtual keyboard on a smartwatch if typing is aided by a decoder. Due to its reliance on decoding for effective text entry, we argue a smartwatch is a good testbed for investigating decoder and interface improvements. In the future we anticipate such harder cases of keyboard decoding will be even more relevant as users transition from mobile phones to wearable devices that rely on noisy sensing techniques.

Error Avoidance via Letter Locking

Many users today have substantial experience with touchscreen keyboards and their associated recognition errors. Even without intimate knowledge of how a decoder works, we conjectured users may often know a priori when an error is about to occur. To test this, we designed a simple error avoidance technique to see if users could anticipate problematic words and change their input behavior. Our *letter locking* method transfers control of the decoding process to the user. When a decoder considers a single observation (i.e. a touch point), it will explore different hypotheses for the observation (e.g. all letters adjacent to the key typed). When the user locks a letter, the decoder is prevented from performing this exploration and the hypothesis is fixed to the key touched. To assist users in locking the right letter, the nearest letter to a user's touch location is shown in a large font. The user locks the letter by maintaining contact for an extended duration. After a time threshold has been exceeded, the preview changes color and the device vibrates to indicate the letter has been locked.

Letter locking allows a user to fluidly switch control between the decoder and the user. A user can take control of single-letter entries and thereby either override decoding altogether for a word by locking every single letter in the word, or steer the decoder by locking a subset of the letters in a word. Using our new phrase set, in Experiment 1 we show users could anticipate difficult words and lock letters to significantly reduce their error rate at a modest reduction in entry rate.

Error Avoidance and Correction via Selection Slots

Virtual keyboards often display a number of selection slots above the QWERTY layout. Users tap a particular slot to take a certain action such as completing the word currently being typed or using the literal text nearest to each tap observation. While the use of selection slots is common in commercial keyboards and some research interfaces (e.g. [7]), we are not aware of any work comparing the efficacy of the many possible designs. It would be onerous to user test the many different options. Instead, in Experiment 2 we conduct simulations on data collected from previous studies on small form-factor virtual keyboards. By simulating optimal use of the slots, our work helps interface designers to decide what slot-based error avoidance and correction features to include.

Tap versus Swipe Selection

As we will see, our offline experiments support including a rich set of error avoidance and correction options. Providing numerous error avoidance and correction features not only consumes valuable screen real estate, but also requires a way for users to select the different options. Ideally these features are selectable with little risk of making a selection error. This helps avoid a cascade of errors that can be extremely detrimental to text entry performance [12].

Virtual keyboards can support the input of entire words by a continuous swipe gesture [34]. They can also support other functionality via swipe such as using a right swipe to recognize the pending user input [29, 26] or to control other keyboard functions [10]. Swipes have also been used to correct speech recognition errors [22, 17, 27]. We wondered if swipes could enhance selecting a small number of actions on a virtual keyboard. In Experiment 3, we explore the impact of swipe versus tap selection on a smartwatch keyboard we call VelociWatch.

Simple versus Complex Design

Our experiments led us to the design of a reasonably complex keyboard squeezed onto a small touchscreen device. Having too many options could cause overheads that might actually reduce real-world performance. For example, users may spend too much time checking prediction slots. Also, users might simply prefer a design with fewer options or a design that consumes less screen space. In Experiment 4, we compare our best design with a simpler one with fewer features.

Contributions

1. We investigate whether, during the heat of text entry, users can predict words that will likely be problematic for a virtual keyboard decoder. Further, we see if users can successfully adjust their input behavior to help the decoder avoid errors.

2. In computational experiments, we compare how to best use a limited number of selection slots to help users avoid or correct errors. Our results inform the design of improved virtual keyboards.

3. We design and iteratively improve a smartwatch keyboard named VelociWatch. VelociWatch incorporates a rich set of features designed to support the input of challenging text. We investigate the impact of tap versus swipe selection of keyboard options. We compare VelociWatch against a more traditional design offering only a few correction features.

RELATED WORK

Mobile text entry methods have been extensively researched [19, 36, 21]. Today virtual keyboards dominate mobile touchscreen devices. Virtual keyboard typing can be improved using decoders. Goodman et al. [6] propose a substitution-only decoder which corrects typing errors using a combination of a touch model and a language model. Kristensson and Zhai [16] propose correcting keyboard typing using geometric pattern matching. Clawson et al. [3] present a correction method for physical thumb keyboards based on keypress timings. An orthogonal approach to decoding keyboard typing is the gesture keyboard [33, 15, 35], which allows users to write by gesturing through all the letters of a word on the keyboard.

Text entry and virtual keyboard typing have also been investigated for smartwatches (see [1] for a survey). Early interfaces focused on techniques to allow users to deterministically select the tiny keys on a smartwatch (e.g. ZoomBoard [23], Swipeboard [2], SplitBoard [11], and DualKey [9]). Other

interfaces such as WrisText [5] and InclineType [8] allow users to enter text using wrist movements. The first study to demonstrate the viability of recognition-based typing on a smartwatch form-factor full QWERTY keyboard was the system VelociTap [29]. VelociTap used a decoder to infer users' intended text. Gordon et al. [7] later demonstrated Watch-Writer, a smartwatch keyboard with decoder-supported tap input, gesture-keyboard input, and word prediction. Watch-Writer uses two suggestion slots. One has the literal text typed by the user while the other "contains the most likely prediction as decided by the decoder." Gordon et al. do not provide a rational for this design. Other smartwatch studies include Yi et al. [32] and Turner at al. [25].

Weir et al. [30] proposed improving decoding using two techniques. The first technique was to use Gaussian Process regression to create a more accurate touch point model. The second technique was to allow users to continuously regulate their uncertainty using pressure. The harder a user pressed on a keyboard key, the less likely the decoder would change the key press into another key. This allowed users to regulate their uncertainty since pressing harder would concentrate the probability mass to be near the contact point while exerting low pressure would spread out the probability mass across many keys and thereby allow the decoder to search wider.

In this paper we also allow users to regulate their uncertainty but our design is different from [30] in two ways. First, letter locking is a discrete binary technique which either fixes the letter or leaves the decoder free to replace it. This means the effect of locking letters is easy to understand. Second, letter locking is accompanied by clear visual and vibration interface feedback. This gives the user certainty that a letter has indeed been locked. Due to these factors, we conjecture users will have an additional sense of agency in controlling the decoder.

Weir et al. [30] also investigated whether users are able to predict whether a decoder would be able to correctly infer a phrase or not. They found that for phrases that were correctly inferred, users generally had a high ability to predict the outcome. However, for phrases that were incorrectly inferred, users tended to overestimate the ability of the decoder.

Text entry methods are typically evaluated using a transcription task in which participants are asked to copy a memorable phrase as quickly and as accurately as possible. MacKenzie and Soukoreff [20] created a standard phrase set to improve the replicability of studies. Their phrase set consists of 500 phrases designed to be memorable, although this was never tested. Vertanen and Kristensson [28] later presented a phrase set consisting of genuine emails written on mobile devices, which were identified by analyzing email signatures in the Enron corpus [13]. A study later showed that there was no significant different in entry or error rates between these two phrase sets [14], although the latter has higher external validity.

There has also been research on sampling memorable and representative phrases across languages [18, 24]. Yi et al. [31] proposed a word clarity metric based on geometric pattern matching [16] for sampling phrases containing words that might be confused due to their geometric proximity. In con-

In-vocabulary phrases	Out-of-vocabulary phrases
I'm prettier than you.	Ready to meet Nanook!
Woke up still Loving y'all.	I voted for Brexit.
I want a Margarita.	Atletico ties it up!
This debate calls for vodka.	Is Rafa playing today?

Table 1. Selection of phrases from our challenging Twitter phrase set.

trast, we present phrases designed to be easy or hard to recognize for a decoder that leverages a statistical language model to guide its search. As a consequence, our phrase set is selected based on in-vocabulary and out-of-vocabulary words and the difficulty of the phrase set is measured using perplexity.

CHALLENGING PHRASE SET

We wanted phrases that would be challenging to recognize while still being memorable. We sourced our phrases from Twitter messages sampled during 2016. We parsed the tweets to find likely sentences based on capitalization and end-of-sentence punctuation. We generated a banned word list of 1,706 obscene words semi-automatically from a variety of sources. We removed sentences containing a banned word.

For text entry evaluations, typically we aim for memorable phrases to avoid participants needing to refer to the phrase during entry. Longer sentences are normally more difficult to memorize, so we removed sentences with more than 10 words. As in the MacKenzie phrase set [20], we focused on sentences with four or more words. Using a word list of 100 K English words, we created a set of 1.04 M sentences where all words were in-vocabulary. We created a second set of 141 K sentences that had a single out-of-vocabulary (OOV) word.

We fielded a random subset of 850 of these sentences to 3–5 Amazon Mechanical Turk workers. We only kept sentences that the majority of workers rated as easy to understand, judged as having no spelling errors, and that workers could type from memory with no errors (ignoring case and punctuation). These were further manually reviewed by one of the authors to remove any remaining offensive sentences. The final phrase set had 213 OOV phrases and 194 in-vocabulary phrases.

Table 1 shows some example phrases. The OOV phrases are the challenging part of the phrase set. We included the in-vocabulary set for comparative purposes. Phrases are in mixed case consisting of the letters A–Z plus apostrophe, comma, question mark, exclamation mark, and period.

Another way to measure the difficulty of text is to measure its *perplexity* under a language model. Perplexity measures the average number of possible next tokens (typically words or characters) given the previous tokens seen. Lower perplexity means the text is generally easier to recognize. We compared the perplexity of our new phrase set against the MacKenzie phrase set [20] and the mem1-5 sets from the Enron mobile data set [28]. For all sets, we removed sentences with numbers and stripped punctuation aside from apostrophe.

To measure average per-character perplexity, we used the character language model employed by our decoder (to be discussed shortly). As shown in Table 2, our TWITTEROOV had the highest perplexity. Thus we anticipate it should be suitably

Phrase set	Perplexity	OOV rate	Words / phrase
TWITTERIV	3.65	0.00%	6.69
TWITTEROOV	5.34	14.71%	6.80
MACKENZIE	4.59	0.07%	5.43
ENRONMOBILE	3.96	0.10%	5.31

Table 2. The per-character perplexity, percentage of words that were out-of-vocabulary (OOV), and words per phrase in different phrase sets.

challenging in comparison to other common phrase sets. We also computed the percentage of words in each set that were OOV with respect to our 100 K word list. All phrase sets had nearly no OOV words except for the TWITTEROOV set.

We also note how ENRONMEM is more predictable on a per-character basis than MACKENZIE. While in prior work [14] the choice of phrase set did not impact user performance in crowdsourced experiments on desktop keyboards, these results suggest language model-based input methods may also want to consider the predictability of phrases. Specifically, recognition-based input systems evaluated on ENRONMEM may appear more accurate in comparison to other systems evaluated on the more challenging MACKENZIE phrases.

APPROACH

Armed with our Twitter phrase set, we set out to investigate interface interventions aimed at helping users avoid or correct recognition errors. Throughout this paper, we focus on input on a smartwatch since in past work small touchscreen keyboards have resulted in relatively high error rates even on easy Enron mobile phrases [29, 26]. This paper presents the following progression of four experiments:

- **Experiment 1** — We compare user and decoder performance both with and without a feature allowing users to lock in particular characters of their input.

- **Experiment 2** — We explore how to use a small number of suggestion slots to enable low error rate and high keystroke savings. This is done in computational experiments on thousands of sentences typed on small virtual keyboards.

- **Experiment 3** — We use the results from Experiment 1 and 2 to inform the design of our smartwatch virtual keyboard VelociWatch. We compare three different options for using tap and swipe actions to select interface features.

- **Experiment 4** — We improve VelociWatch based on Experiment 3. We compare our keyboard design with a traditional design with only a few correction options.

EXPERIMENT 1: LETTER LOCKING

The goal of this study was to investigate if users could anticipate words likely to cause a recognition error and modulate their behavior to avoid them. Further, we wanted to see whether this additional user signal could help our decoder.

Keyboard design

We designed a virtual keyboard for the Android Sony Smart-Watch 3. This watch has a screen area of 29 mm × 29 mm with a resolution of 320 × 320 pixels. The watch has a 4-core 1.2 Ghz ARM CPU with 512 MB of memory. Recognition was performed locally on the device.

The keyboard contained the letters A-Z plus apostrophe. There was no spacebar key. As shown in Figure 2, the keyboard occupied the lower portion of the screen and measured 29 mm × 13 mm. Each key was denoted by white text on a grey background with no explicit visual boundary between keys. This resulted in an effective key size of 2.9 mm × 4.3 mm.

The text result area above the keyboard shows previously recognized text as well as the nearest keys for the current unrecognized input sequence (Figure 2a). Swiping right causes the current tap sequence to be recognized (Figure 2b). While recognition was in progress, the screen background turns green and no input is accepted until it completed.

When a user's finger is in contact with the screen, the current nearest key is displayed in a large font over the result area (Figure 2c). This allows the user to reposition their finger despite the visual occlusion caused by their finger. If the touch event lasts for 500 ms or longer, the letter popup turns orange and the watch vibrates (Figure 2d). This signals that whatever letter is under a user's finger when they lift up will be locked during the decoder's search and not subject to auto-correction.

Swiping left deletes the previous tap from the observation sequence and deletes the nearest key label from the result area. Swiping up moves to the next task. Swipes had to be 3 mm or longer to be recognized. Swipe direction was determined by the angle between a swipe's first and last point. Taps had to be within 3 mm of the top of the keyboard area to register. Swipes could occur anywhere on the screen.

In this study, users could not delete or otherwise correct recognition results (e.g. via left swipe or by implementing a suggestion bar). We chose to do this to understand the performance of letter locking in isolation rather than how it might perform in combination with other error correction features.

Decoder

Our decoder is based on the noisy tap decoder VelociTap [29]. The original version of VelociTap inferred the most probable sentence given a sequence of two-dimensional tap locations. Here we use a modified version that recognizes input progressively, supporting input of a variables number of words (as in [26, 4]). See [29, 26] for details about the decoder's operation. Here we highlight just the changes we made to support letter locking and the specific language models we used.

To support letter locking, each tap observation was augmented with a field indicating if a tap should be treated as certain. This field was set by the virtual keyboard whenever a touch event lasted over a threshold time. One or more taps in a word could be locked. In the case of locked taps, we allowed the keyboard model to only generate the key closest to the touch up location. We also prevented the decoder from deleting locked observations. This ensured all locked letters had to appear in the recognition result. We also disallowed insertions between consecutive locked letters. This prevents the decoder from inserting guesses that might be probable under the language model, but which may contradict a user's intent. For example, a user might lock the "p" and "c" in "snapchat" hoping to get a single word. In this case we want to avoid the decoder being allowed to insert a space between the locked letters.

Figure 2. Example of writing "ready to meet nanook" in our first study: (a) The keyboard has already recognized "ready to", the user has tried to type "meet" but was somewhat inaccurate. **(b)** After swiping to the right, the nearest key text is replaced with the correct recognition result. **(c)** If a finger is down, the nearest key appears in a large font. **(d)** After a period the letter changes to orange signaling it has been locked and not subject to auto-correction. **(e)** After locking the remaining letters, the user correctly obtains "nanook".

We trained our language models as in [26]. Our word model has 588 K n-grams and a gzipped ARPA text size of 5.5 MB. In Experiment 1, we used a character model with 766 K n-grams and a size of 6.3 MB. In Experiment 2 and 3, we used a slightly bigger character model with 963 K n-grams and a size of 9.0 MB. We found this bigger model improved recognition accuracy on the smartwatch input collected in Experiment 1.

Study Procedure

We recruited 16 participants via convenience sampling. Participants took part in an hour session and were paid $10. Participants were aged 18–27 (mean 19.1). 10 participants identified as male, 2 female, and the rest did not answer. 15 participants were right-handed. 10 participants had never used a smartwatch, 3 used one occasionally, and 3 used one frequently.

In Experiment 1, participants entered memorable phrases from our Twitter phrase set. Due to the small size of the smartwatch screen used in our study, we further limited the Twitter phrases to those with six or fewer words. We also removed phrases with acronyms as we worried users might incorrectly assume the lock feature was only for spelling out acronyms. In the end we obtained 43 OOV phrases and 81 in-vocabulary phrases.

Experiment 1 was a within-subject experiment with two counterbalanced conditions. In the NOLOCK condition, the feature allowing letters to be locked was disabled. Participants could still touch and hold to receive visual feedback of the key they were over, but the resulting touch up location was probabilistically decoded. In the LOCK condition, participants could touch and hold to lock individual letters. Participants were instructed they could lock one, several, or all the letters in a word. In LOCK, participants were reminded on the prompt screen that they could tap and hold to lock letters.

Participants wore the watch on their non-dominant arm and rested their arm on a desk. At the start of Experiment 1, participants practiced in both condition writing two OOV and two in-vocabulary phrases. Practice tasks throughout this paper were excluded from analysis. In each condition, participants received 6 OOV phrases and 6 in-vocabulary phrases. Participants saw a random subset of the phrase sets and never saw the same phrase more than once. The OOV and in-vocabulary phrases were mixed together at random.

Participants could spend as long as they wanted memorizing a phrase. The phrase disappeared and could not be referred to again once input began. After completing each transcription

Figure 3. Long tap (%), error rate, and entry rate in Experiment 1.

task, the participant was shown the reference text, the recognition text, and their entry and error rate. If the error rate was above 5%, it was shown in red and the watch vibrated twice.

Results

Figure 3 displays the main results. Overall, participants used the lock feature. 12% of taps in LOCK were *long taps* lasting over 500 ms compared to only 0.4% of taps in NOLOCK. This difference was statistically significant: dependent t-test, $t(15) = 8.41$, $r = 0.91$, $p < .001$.

We measured the *error rate* using Character Error Rate (CER). CER is the number of character insertions, deletions, and substitutions required to change the recognized text into the reference text, divided by the characters in the reference. Their use of letter locking reduced their error rate: 6.2% CER in NOLOCK versus 3.3% in LOCK. This difference was significant: $t(15) = -4.21$, $r = 0.74$, $p < .001$.

We measured *entry rate* using words-per-minute (wpm) with a word being five characters including space. We calculated entry time from the first tap on the keyboard screen until the recognition result was displayed. Recognition time was negligible, 0.055 s in LOCK and 0.063 s in NOLOCK. As might be expected, locking letters reduced input speed: 20.9 wpm in LOCK versus NOLOCK at 23.2 wpm. This difference was significant: $t(15) = -3.86$, $r = 0.71$, $p < .01$.

The use of left swipe to backspace a previous tap event was infrequent in both conditions, 0.087 backspaces per character in NOLOCK and 0.081 in LOCK. This difference was not statistically significant: $t(15) = -0.53$, $r = 0.14$, $p = 0.604$. This indicates that despite participants often seeing visual feedback of erroneous nearest key labels, participants tended to trust the auto-correction algorithm.

For tasks in LOCK where the words in the phrase matched the number of recognition events, we determined which word (if any) a participant locked. We also determined if all the letters in the word were locked or just a subset. 65% of the time participants locked some, but not all of a word's letters. The most frequent words that had all their letters locked were, in decreasing order: *bourre, brembo, auchinleck, haast, grigson, brofist, europe, delmon, evra, paak*. The most frequent in which any letter was locked were: *brembo, auchinleck, grigson, knapsacking, bourre, paak, europe, deano, luton, delmon*. With the exception of *europe* and *luton*, all these words were OOV with respect to our 100 K vocabulary. We conjecture participants mistakenly thought these two words needed locking to force recognition in lowercase. In fact this was not really a problem since our phrases and system always used lowercase.

We further analyzed participants' lock letter behavior in the LOCK condition. We measured the percentage of in-vocabulary and out-of-vocabulary words where participants locked some letters (i.e. one or more) in a word and words where participants locked every single letter. Participants locked some letters in 4.8% of in-vocabulary words while they locked some letters in 75.6% of OOV words. This difference was significant ($t(15) = -9.79, r = 0.93, p < .001$). Participants locked all the letters in 2.1% of in-vocabulary words while they locked all the letters in 42.5% of OOV words. This difference was significant ($t(15) = -5.71, r = 0.83, p < .001$).

To lock a letter, participants had to precisely target a key. This alone could lead to a lower error rate. To measure if our decoder changes to support locking actually improved recognition accuracy, we ran offline experiments on the data from the LOCK. As in the user study, if the lock letter feature was turned on, the decoder locked the specific letters in a word where a user's tap exceeded the time threshold. If the lock letter feature was turned off, the decoder treated locked taps as normal probabilistic ones. We found turning the decoder feature off increased the error rate from 3.3% to 5.5%. Thus it was pinning portions of the observation sequence down that helped improve recognition accuracy.

Thus it appears without any explicit instructions, users could accurately predict the words that might be problematic for an auto-correcting virtual keyboard. This could stem from previous exposure to auto-correction errors using virtual keyboards on other mobile devices. It could also be that participants are singling out uncommon words based on their knowledge of English. An interesting observation is that participants often lock some but not all the letters in difficult words. We will analyze this in more detail in our final study.

Open comments from participants were in general supportive of the lock feature such as "More effective with the ability to lock characters" and "Lock in is a vital feature for strange words and names." However some noted locking felt slow or suggested alternatives, e.g.: "I wish there was a way to lock a specific word after finishing it rather than locking each letter" and "I liked the lock feature. I just wish it was faster." In Experiment 3, we address these issues by lowering the time threshold and adding a way to select the literal text typed.

EXPERIMENT 2: SELECTION SLOT DESIGN
In this section, we conduct computational experiments to help design our smartwatch keyboard. We explore four slot options for aiding users to avoid and correct recognition errors:

- **Prefix slots** — Word completions based on the currently noisy prefix input of a word. A user's taps thus far are treated probabilistically during the search for the most likely word completions.

- **Best slots** — Recognition alternatives based on all the pending taps. This is similar to a prefix slot other than the decoder is told to assume the taps represent an entire word and not necessarily just a word prefix.

- **Likely slots** — These slots use whatever hypotheses have the highest probability regardless of whether they are prefix completions or recognition alternatives.

- **Literal slot** — The text of the letters nearest to each tap.

Simulation and Test Data
We simulated a hypothetical user who made optimal use of any available selection slots to try and obtain a sentence's reference text. For purposes of these experiments, we assume no use of other correction features such as backspacing and re-typing errors. We assume prefix predictions are made before even the first letter of a word is typed. Predictions use the previous selected words as context to the language model. If the simulated user is unable to get the desired reference word during input, we use the most likely hypothesis. This simulates leaving such errors uncorrected, potentially negatively impacting the language model's performance on future words.

We measure performance using two metrics. The first is the character error rate of the final text. The second is the potential *keystroke savings*. Keystroke savings (KS) is calculated as $KS = \left(1 - \frac{k_p}{k_a}\right) \times 100\%$ where k_p is the keystrokes required with word predictions and k_a is the keystrokes without predictions. Higher keystroke savings is better. We assume slot selection requires one keystroke and adds any following space.

We ran our simulation on 3,158 sentences of virtual keyboard data from the SMALL and TINY keyboard conditions of [29] and all conditions of [26]. Note that some of these conditions involved users typing multiple words without input separating them. We converted the data to word-at-a-time input by force-aligning the input sequences with the reference transcript.

Results
We simulated all possible ways to set a given number of slots to the prefix, best, likely, or literal options. The literal option could either be included or not. If a candidate design had *N* slots of some type, we used the *N* most likely hypotheses of that type. We never included the same word in multiple slots so when filling a slot of a given type, we continued down the hypothesis list ordered by probability until we found a new word. Before the first tap of a word, there were no best or literal options, so we filled all slots with prefix completions.

Figure 4 shows the performance envelope of different slot designs. As expected, using more slots provides improved performance, but gains are marginal past five slots. The points
Figure 4. Performance envelope of 2–6 slot virtual keyboard designs.

Likely	Prefix	Best	Literal	KS	CER
0	0	2	No	8.4%	3.7%
0	0	1	Yes	8.1%	4.1%
0	1	0	Yes	27.6%	6.8%
1	0	0	Yes	27.6%	6.8%
0	0	4	Yes	12.9%	3.3%
2	2	1	No	40.2%	3.5%
3	**0**	**1**	**Yes**	**38.5%**	**3.6%**
1	4	0	No	41.4%	3.8%

Table 3. A selection of possible two and five slot designs. We selected the configuration in bold for our smartwatch keyboard.

in the lower left of Figure 4 represent designs where most or all slots are best slots. This resulted in poor keystroke savings but provided the lowest error rates for a given number of slots. Note that some keystroke savings was still possible for these cases due to our use of prefix completions at the start of words.

For a given number of slots, the point with highest KS used most or all slots for prefix completions. The use of a literal slot in most cases resulted in worse performance in terms of CER and KS. This is likely due to our test data consisting largely of Enron mobile phrases that had almost no OOV words.

Table 3 shows a selection of operating points for two and five slots keyboards (a complete list appears in our supplementary material). For our keyboard, we decided to go with five slots as it provides the majority of potential gains. Five slots also did not lose much performance when a literal slot was included. This was important as we wanted to compare a literal slot against our new lock letter technique. For five slots, the best option was to use three likely and one best slot.

In Experiment 4, we will compare against a simpler two slot keyboard. With only two slots, using a literal slot requires choosing either to optimize keystroke savings or error rate. Using a likely or prefix slot and a literal slot provided nearly identical performance. We decided on using a likely slot as it allows word completions early in entry but hopefully converges to a best hypothesis as the entire word is typed.

EXPERIMENT 3: VELOCIWATCH
Based on Experiment 1 and 2, we designed a predictive virtual keyboard named VelociWatch. VelociWatch provides five text suggestions as well as a backspace action. In Experiment 3, we compare using swipes versus taps to select these options. We conjectured given the limited interaction size of a smartwatch, swipe selection would be more accurate than tap selection.

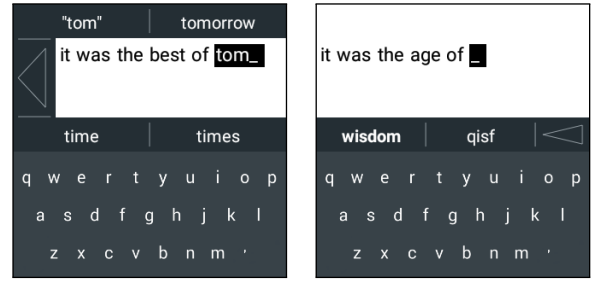

Figure 5. The VelociWatch keyboard that uses five slots (left). The two slot keyboard used in Experiment 4 (right).

Keyboard Design
We placed prediction slots in the four corners above and below the text area (Figure 5 left). This allowed an easy mapping between the visual location of the slots and swipe selection actions. Swiping up and left anywhere on the screen selected the top-left suggestion, swiping up and right selected the top-right, and so on. This led us to put the backspace key on the left hand side of the keyboard to correspond to left swiping to erase the last letter. The top-left slot was used for the literal slot. Similar to some commercial keyboards, we placed the literal text in double quotes to denote this. The most likely prediction was in the upper-right, the second most likely in the bottom-left, and the third most likely in the bottom-right.

We displayed the best recognition result in highlighted text in the text area. We worried placing a spacebar at the bottom of the keyboard would cause accuracy problems due to size limits, and its proximity to the sensor edge and other letters. Spaces are commonly typed so having a sure way to type them is important, especially when other letters are treated probabilistically. We decided on a novel design in which the text area served as an implicit spacebar. This gave a large target away from the screen edge. It also felt natural to tap the highlighted best recognition hypothesis in order to select it.

As in Experiment 1, dwelling in the keyboard area resulted in a large preview of the letter. Based on feedback from Experiment 1, we lowered the lock letter time threshold to 250 ms. The locked letters influenced the decoders search and thus slots only showed suggestions complying with any locked letters. Before any input for a word, all four slots were populated with likely words given the previous text context. All slots updated every time the user typed a key or backspaced. Recognition was performed on a separate thread so typing could proceed without waiting for recognition. Predictions were populated on average 91 ms after a key press.

Each prediction slot was 14 mm×3.3 mm. The backspace button was 4.2 mm×8.3 mm. The text area was 24 mm×8.3 mm. The text area could show three lines of text. After selecting a prediction, backspace, or the pending best text, the selected element would flash green to show which action was taken.

For this experiment, we tuned the parameters of VelociTap on 1,104 sentences of data collected on a Sony SmartWatch 3 in [26]. We used data from conditions in which participants had tapped one or two words prior to a recognition request.

Study Procedure

We recruited 24 participants via convenience sampling. None had participated in the previous study. Participants took part in one-hour session and were paid $10. 22 participants were right-handed. Participants were aged 18–22 (mean 19.3). 15 participants identified as male, 6 female, and the rest did not answer. 13 participants had never used a smartwatch, 8 used one occasionally, and 3 used one frequently. 18 participants had not entered text on a smartwatch, while 2 used speech recognition, and 4 used tap gestures on a QWERTY keyboard.

This was a within-subject experiment with three counterbalanced conditions. In the TAP condition, the best, four likely slots, and backspace button all had to be tapped. In the SWIPE condition, the best slot was selected by right swipe, the backspace was selected by left swipe, and the four likely slots were selected by diagonal swipes. In the HYBRID condition, the best slot was selected by right swipe, the backspace was selected by left swipe, and the four likely slots were tapped.

Participants were first shown a short video demonstrating all the features of VelociWatch. This video showed both the swipe and tap actions for all features. At the start of each condition, participants were told whether swipe or tap was enabled for each feature. Participants wrote OOV and in-vocabulary Twitter phrases as in Experiment 1 with the exception that we reduced the phrases to two in practice and 10 in evaluation. After each condition, participants completed a questionnaire.

Results

Figure 6 shows the main results. Overall, participants wrote at about the same speed in all three conditions: 17.7 wpm in TAP, 17.8 wpm in SWIPE, and 17.4 wpm in HYBRID. This difference was not statistically significant: repeated measures ANOVA, $F_{2,46} = 0.26$, $p = 0.78$. The entry rate across all conditions for the in-vocabulary phrases was 21.3 wpm while for OOV phrases it was 13.9 wpm. Thus it appears users are either slowing down their typing or having to perform corrective actions for the more difficult text.

We measured the error rate of the final text of each task after any user correction. Error rates were overall low: 3.2% CER in TAP, 3.4% in SWIPE, and 2.1% in HYBRID. This difference was not significant: $F_{2,46} = 2.13$, $p = 0.13$. The error rate across all conditions for the in-vocabulary phrases was 2.0% CER while for OOV phrases it was 3.7%. This could mean that despite the error correction features, participants still could not obtain the specified text. Alternatively, harder phrases may have been more difficult to remember for participants.

We anticipated the small slot targets would result in more backspacing to correct errors resulting from errant selections. This did not seem to be the case, backspaces per character was similar in all conditions: 0.137 in TAP, 0.137 in SWIPE, and 0.151 in HYBRID. This difference was not significant: $F_{2,46} = 4.16$, $p = 0.66$. There was an increase in backspacing to 0.142 compared to 0.086 in Experiment 1 (averaged across conditions). Thus it appears participants were backspacing to some degree to correct erroneous slot selections.

3.3% of taps were over the lock letter threshold of 250 ms. This is a marked decreased from the 12% observed in the LOCK

Figure 6. Entry rate, error rate, and backspacing in Experiment 3.

condition of Experiment 1. This is likely due to competing ways to obtain the correct text via the slots. This feature appeared popular with some users but not others; half locked 0.7% or less of letters while the other half locked 1.2–13.5%.

Averaged over all conditions, we found participants selected the best slot 68% of the time, one of the likely slots 10% of the time, and the literal slot 22% of the time. For in-vocabulary phrases, this ratio of best, likely, and literal slot usage was 71%, 3%, and 26% respectively. But for OOV phrases, it was 65%, 16%, and 19%. While the literal slot was not that advantageous in Experiment 2, on more difficult text it becomes an important feature for avoiding the auto-correct trap.

VelociWatch allowed the entry of multiple words without a space. 95.9% of slot selections consisted of a single word, while 4.2% had multiple words. Just because the decoder inferred a multi-word result does not mean that was a user's intent. It could be a mistake by the decoder. We found 1.5% of the selections were a correct multi-word substring of the reference phrase. This indicates that VelociTap may have inserted spaces too freely. Further, only 5 participants selected correct multi-word results more than 1% of the time. These results suggest most users prefer a word-at-a-time entry approach.

When a likely slot was selected, we tallied how many taps a participant made prior to the selection: 0 taps 8.4%, 1 tap 6.5%, 2 taps 10.2%, 3 taps 14.6%, 4 taps 19.5%, 5 taps 11.6%, 6 taps 8.6%, 7 or more 17.2%. Thus occasionally making predictions before the start of the word was useful. Participants seemed to type a number of letters prior to selection.

On a 7-point Likert scale where 7 is strongly agree, the mean rating for the statement "I entered text *quickly*" was 5.2 in TAP, 5.4 in SWIPE, and 5.6 in HYBRID. This difference was not significant, Friedman's test, $\chi^2(2) = 1.13$, $p = 0.57$. The mean rating for the statement "I entered text *accurately*" was 5.5 in TAP, 5.1 in SWIPE, and 5.5 in HYBRID. This difference was not significant, Friedman's test, $\chi^2(2) = 1.19$, $p = 0.55$.

In open comments, some participants preferred swiping while other preferred tapping. A few participants commented they swiped when they were suppose to tap or vice versa. At the end of the study, participants specified their preferred method. 38% selected HYBRID, 33% selected SWIPE, and 29% selected TAP. We asked participants to comment on how they dealt with difficult text. 15 participants commented specifically that they used the letter lock feature. Less common themes included checking the suggestions and using the literal text.

8

EXPERIMENT 4: TWO SLOT KEYBOARD COMPARISON

Based on Experiment 3, we decided to enable both swipe and tap functionality since some participants like tapping while others liked swiping. We also added a feature allowing users to delete an entire word at a time since we observed participants frequently backspaced entire words. This resulted in a keyboard with a range of features. In this section, we investigate the performance of VelociWatch and a simpler design.

Keyboard Design

The simpler keyboard has three options: the most likely word hypothesis on the left, the literal text in the middle, and a backspace button on the right (Figure 5 right). The most likely hypothesis could be either a prefix completion or a recognition alternative. We search for both types of hypotheses and use the one with highest log probability. The backspace button deletes all pending letters for the current word. If there are no pending letters, it deletes the previous word. Note this design has no way to delete an individual character. The design can also result in a user getting stuck with an incorrect prefix completion with no option except to start the word over.

We reduced the available input options and reduced visual clutter in a number of ways. We did not allow multi-word input. We also did not populate the slots until the first letter was typed. We turned off the lock letter feature and the key preview. The keyboard area was the same as VelociWatch. Prediction slots were 11.4 mm×3.3 mm. The backspace key was 5.5 mm×3.3 mm. We displayed up to three lines of text.

Study Procedure

We recruited 14 participants via convenience sampling. None had participated in previous studies. Participants took part in one-hour session and were paid $10. 13 participants were right-handed. Participants were aged 18–22 (mean 19.2). 10 participants identified as male, 3 female, and 1 did not answer. 6 participants had never used a smartwatch, 7 used one occasionally, and 1 used one frequently. 10 participants had not entered text on a smartwatch, while 2 used speech recognition, and 1 used tap and swipe gestures on a QWERTY keyboard.

This was a within-subject experiment with two counterbalanced conditions: In the VELOCIWATCH condition, participants used the VelociWatch keyboard. In the TWOSLOT condition, participants used the two slot keyboard.

At the start of the experiment, we showed participants a video demonstrating the keyboard assigned to their first condition. They then wrote four practice phrases using that keyboard. We then showed a video demonstrating the other keyboard and they wrote four practice phrases with the second keyboard. Participants wrote 10 OOV and 10 in-vocabulary Twitter phrases using a procedure similar to the previous experiments. After each condition, participants completed a questionnaire.

Results

Figure 7 shows the main results. Much to our surprise, participants wrote fastest in TWOSLOT at 20.6 wpm versus VELOCIWATCH at 17.3 wpm. This difference was statistically significant: $t(13) = 3.78$, $r = 0.72$, $p < 0.01$. Averaged across conditions, entry rate was substantially faster for in-vocabulary

Figure 7. Entry rate, error rate, and backspacing in Experiment 4.

phrases at 22.3 wpm versus 15.5 wpm for OOV phrases. We conjecture overheads associated with monitoring the additional slots or locking letters may have contributed to the slower entry rates in VELOCIWATCH.

Error rate was similar in both conditions with a CER of 3.0%. This difference was not significant: $t(13) = -0.11$, $r = 0.03$, $p = 0.91$. Averaged across conditions, error rate was substantially higher for OOV phrases at 4.3% versus 1.7% for in-vocabulary phrases. It is surprising that despite having only a coarse-grained word deletion feature, participants in TWOSLOT achieved acceptable error rates on challenging text.

Both interfaces has an action to delete all pending input or a previous word. This feature was used frequently at 1.4 times per task in TWOSLOT 1.4, but was only used 0.03 times per task in VELOCIWATCH. It seems participants either preferred to backspace one letter-at-a-time, or did not learn this feature. Only VELOCIWATCH allowed backspacing of individual letters. Participants used 0.12 backspaces per output character, similar to what we observed in Experiment 3.

In VELOCIWATCH, participants used long taps to lock letters 3.0% of the time, similar to Experiment 3. Participants selected the best slot 46.4% of the time, one of the likely slots 38.4% of the time, and the literal slot 15.2% of the time. In TWOSLOT, participants selected the likely slot 61.9% of the time and the literal slot 38.1% of the time. It seems without other correction features, participants in TWOSLOT were relying more on careful typing and the use of the literal slot.

In VELOCIWATCH, 91.9% of selections consisted of one word while 8.1% had multiple words. The majority of multi-word recognitions matched the target text, 5.7% of total selections. This was an increase from Experiment 3. This was driven by four participants who used multi-word input to good effect.

In VELOCIWATCH, 60.3% of selections used tap while 39.7% used swipe. For tap selections, 37.8% were for a suggestion slot, 27.7% for the best slot, and 34.5% for backspace (character or word). For swipe sections, 10.0% were for a suggestion slot, 6.2% for space, and 83.7% for backspace. So in an interface that allowed either tap or swipe, participants tended to use tap, but swipe use was still frequent especially for erasing previous characters. This suggests virtual keyboard designer may want to consider adding swipe actions for some operations.

We analyzed all the individual recognition events that had one or more taps in VELOCIWATCH. 4.8% of words had at least one letter locked. 1.5% of words had all their letters locked. Table 4 shows some samples of each case.

Input	Target	Input	Target
knovKAERT	knockaert	OZZY	ozzy
breXit	brexit	HAAST	haast
xgOPT	chopt	BROFIST	brofist
wEEzer	weezer	SEVCO	sevco
DESIIgner	desiigner	AUCKENLECH	auckenlech

Table 4. Words with locked letters and the target word. Locked letters appear in capitals. Other input letters show the letter nearest each tap.

On a 7-point Likert scale where 7 is strongly agree, the mean rating for the statement "I entered text *quickly*" was 5.3 in VELOCIWATCH and 5.1 in TWOSLOT. This difference was not significant, Friedman's test, $\chi^2(1) = 0.08$, $p = 0.78$. The mean rating for the statement "I entered text *accurately*" was 5.0 in VELOCIWATCH and 4.4 in TWOSLOT. This difference was not significant, Friedman's test, $\chi^2(1) = 0.28$, $p = 0.59$.

8 participants preferred VELOCIWATCH while 6 preferred TWOSLOT. Participants preferring VELOCIWATCH commonly cited the lock letter, swipe, more suggestions, and character backspace as the reason. Participants preferring TWOSLOT said it was simpler, had fewer options to scan, and resembled familiar keyboards. Common strategies mentioned for difficult words included typing slowly and locking letters.

DISCUSSION AND LIMITATIONS

The most interesting finding of this work was that the simple two slot keyboard out-performed our more feature-rich keyboard that we painstakingly designed via computational and user experiments. It did this for the input of difficult text in which half the phrases involved OOV words. This is quite remarkable since these OOV words were unlikely to be correctly predicted by the decoder. This left the user with only one choice: tap every letter of a word correctly with zero mistakes on a smartwatch. Due to the keyboard only having a word-level backspace, any errant tap required starting the entire word over. On just the OOV phrases, participants achieved an acceptable error level of 4.4% while still typing at 17 wpm.

When asked how they handled difficult words, 8 of the 14 participants mentioned they slowed down. This is corroborated by an analysis of the log files. When entering in-vocabulary words, participants wrote at 23.0 wpm. When entering OOV words, they slowed to 14.5 wpm. For OOV words, participants used the literal 84.7% of the time. For in-vocabulary words, they only used the literal 33.2% of the time. So it appears participants were able to quite often enter OOV words simply by carefully tapping each letter and selecting the literal slot. This suggests the so called "fat finger" problem may be overstated. It appears that even on a small virtual keyboard, users were able to exactly target all the letters of many words without the help of an auto-correct algorithm.

Our participants consisted of university-age students with substantial touchscreen typing experience. When rating the statement "I frequently enter text on a mobile phone", participants mean rating was 6.7 (where 7=strongly agree). Despite half our participants having never used a smartwatch, they seemed to quickly learn to accurately target keys on its small touchscreen. Participants also seemed quite capable of anticipating auto-correction problems. This is likely a result of substantial first-hand experience. It remains to be seen if such precise typing or error awareness holds for a broader population.

Our studies all consisted of a single one-hour session. It is possible VelociWatch would become faster with practice. However, it is also possible inherent cognitive overheads related to monitoring more suggestion slots or deciding what correction feature slowed performance. These aspects were not modeled as part of the computational-driven design of our interface. It would be interesting, but challenging, to incorporate such aspects into the simulations. Another possibility is that VelociWatch may enable faster input if restricted to single word predictions. Multiple word input was seldom used by participants; we conjecture most participants have more experience with word-at-a-time entry.

We designed our keyboard for inputting challenging text on a small touchscreen. Our choices may not be optimal for larger devices or for the input of more predictable text. There is also scope for designs between our two keyboard interfaces. Participants indicated they would have liked some of the features of VelociWatch in the simpler two slot keyboard. This included the ability to backspace individual letters, the option to swipe, and the ability to lock letters. Adding a targeted set of such features could result in a keyboard that performs better on challenging text than the two designs we tested.

CONCLUSIONS

We presented a new phrase set of memorable Twitter messages that provides challenging text for evaluating text entry interfaces. We investigated a new letter locking feature that allows users to take control of the recognition process. In our first user study, we found that users had a good sense of what words would be difficult for the auto-correct algorithm. Letter locking provided improved recognition accuracy with modest reductions in entry rate. We used data from thousands of sentences typed on small virtual keyboards to explore what suggestions to offer on a virtual keyboard. We found using a literal slot, the best recognition hypothesis, and three likely alternatives offered the best potential of fast and accurate input.

Combining our letter locking feature and our selection slot findings, we designed a smartwatch keyboard. We investigated using swipes rather than taps for selecting the keyboard's suggestions. We also tested using the text area as a large implicit spacebar. In our second user study, participants performed similarly using swiping or tapping. User opinion was mixed with some preferring swiping and some preferring tapping.

In our final user study, we compared our VelociWatch keyboard against a simpler keyboard with only two suggestion slots. Empirically, the simpler keyboard was faster at 20.6 wpm compared to our keyboard at 17.3 wpm. Both keyboards achieved a low corrected error rate of 3%. We think this is impressive performance given the challenging nature of our phrases and the noisy input resulting from a small touchscreen. Despite the somewhat slower entry rate, participants perceived VelociWatch to be of similar speed and accuracy. The majority subjectively preferred VelociWatch. The performance of the simpler keyboard suggests accurate typing for occasional difficult words may be possible even without auto-correction.
